Abstract

In pasture breed condition helminth infection are common especially during late spring and autumn months. Research of goats and sheep parasites was made systematically last 10 years in Serbia. Most of the research related to gastronintestinal and something less about lung helminth infection. The research was carried out on several locations in Serbia in the period and included goat and sheep herds in the area of carried out in north, northeast, eastern, southern and south-eastern part of Serbia and at Belgrade area. We examined fecal samples using the Berman method. Slaughtered or dead animals we examined by necropsy and adult parasites separated from the lung section. Determination of adult and larval stage of parasites was based on the morphological characteristics. During our examination most abundant species was Dictyocaulus filaria, followed by Protostrongylus rufescens, Cystocaulus nigrescens and Muellerius capillaris.

Key words: small ruminants, lung worm, Serbia.

INTRODUCTION

The grazing diet allows the permanent contact of small ruminants with intermediate hosts and the eggs and larval forms of the parasite. From these reason parasitic infections are present worldwide in a large number of herds (Berrag and Urquhart 1996; Alemu et al., 2006; Geurden and Vercruysse, 2007; Pavlovic et al., 2009a, 2012, 2013; Alasaad et al., 2010).

Lungworms of domestic ruminants are nematodes that belongs to the phylum Nemathelmenthes commonly named as round worms; classified under the super family Trichostrongyloidea and Metastrongyloidea (Tewodros, 2015). Of which, Dictyocaulus and Protostrongylus are causes of lungworm infection in ruminants (Taylor et al., 2007; Palic, 2001; Pavlovic et al., 2009b, 2010a). They induce verminous pneumonia which was a significant health problem of sheep and goats Pulmonary strongilidés of small ruminants are most commonly occur in pastures with lush vegetation (Pavlovic et al., 2009b, 2010a). Pasture infectivity is related to rainfall which stimulates the activity of both the larvae and the mollusk. Moisture is essential for the survival and development of the larvae. The larvae is active at moderate temperature of 10-21°C. Larvae survive best in cool, damp surroundings especially when the environment is stabilized by the presence of long herbage of free water.

In our paper we present the results obtained on the prevalence of pulmonary strongilides in sheep and goats in Serbia, based on research done in the last few years.

MATERIALS AND METHODS

Investigations performed in period 2012-2018 and included 430 herds of goats and sheep in the area of Belgrade, Stara Planina, north-eastern, central and southern part of Serbia and in Vojvodina.

In total, 4300 fecal samples were examined by the Berman method. At the same time, we have done the autopsy of 387 animals on the slaughter line or after death. After that routine necropsies of the lungs were performed. The helminths within the particular lesion were found and their species were determined under the microscope.

Determination of parasites larvae and adult parasites was based on its morphological characteristics (Dunn, 1978; Euzeby, 1981).
RESULTS AND DISCUSSIONS

During our studies, infection with pulmonary strongilides was recorded in 327 (76.04%) herds. Based on the autopsy we revealed the presence of *Dictyocaulus filaria* (47.02%), *Protostrongylus rufescens* (74.01%), *Muellerius capillaris* (37.20%) and *Cystocaulus nigrescens* (19.12%). On the basis of autopsy and coprological examination average prevalence of *D. filaria* was 60.52%, *P. rufescens* 74.01%, *M. capilaris* 39.22% and *C. nigrescens* 19.31% (Figure 1).

*Dictyocaulus filaria* was occurred at all small ruminants heard from all part of country and prevalence was from 12.24 to 60.52%. The highest prevalence is observed in the herds in Vojvodina, north and southeastern Serbia where predominate flat plain pastures. Due to microclimatic conditions, the infection usually occurs in the period April-May when the largest number of animals are grazing. This has been confirmed by research on grass on pastures for the presence of larvae of parasites (Regasa et al., 2010; Pavlovic et al., 2010a; Ivanovic and Pavlovic, 2015). Parasites are predominant at herd grazed at hill side of mountains, especially at eastern, central and southern part of Serbia. *Protostrongylinae* are biohelminthes and need intermediate hosts for their development - snails and slugs (Diez-Baños et al.,1989; Manga and Morrondo, 1990; Morrondo-Pelayo et al.,1992). During ours examination in pastures in various parts of Serbia we concluded that the most common intermediate hosts are *Abeda frumenta, Arion ater, A. subfuscus, Cepae vindobenensis, Helix aspersa, H. pomatia, Chondrula tridens, Fruticola fruticum, Derocercas reticulatum, Eucophalia strigella* and *Helicella obvia*. Due to microclimatic conditions, the infection usually occurs in the March and April when the largest number of intermediate host are preset at pasture (Pavlovic et al., 2010b).

During examination most abundant species was *Protostrongylus rufescens* occurred on 21.93 to 77.21%. These nematodes live in bronchioles and alveoli, are reddish in colour and relatively small - the male is 16-28 mm long and the female is 25-35 mm long (López et al., 2011). The parasitic lesions established in the present study were located within the caudal lung lobes and were disseminated mainly within the dorsal subpleural parenchyma (Figure 3).
From the genus *Cystocaulus* we occurs *C. nigrescens*. Adult parasites live in the pulmonary parenchyma (Mengestom, 2008). The parasites are gray-white in colour. Males are 18-24 mm long and female's 40-50 mm. Prevalence are ranges from 12.22 to 39.22%. On diaphragmatic lobes we found cone-shaped granulomas in lung tissue that varied in size, color, and degree of consolidation (Hubado, 2010; Domke et al., 2013). They contain sexually active parasites with a mass of eggs and larvae. The nodules were as large as the head of a dark brown to black if *Cystocaulus* sp. was present (Figure 4).

From the genus *Muellerius* occurs *Muellerius capillaris*. Parasites live in the bronchioles and alveoli. The body of the parasite is thin white. The prevalence ranges was from 4.23 to 19.31%. The lung lesions in goats infected with *M. capillaris* were nodular, firm, and gray located in the dorsal surface of the caudal lung lobes (Tenaw and Jemberu, 2018). The lesions in the lungs of sheep were more severe, regardless of the animals’ age. In the most cases they were not formed as nodules and were dark grey to black areas affecting a large part of the lung surfaces (Figure 5).

**CONCLUSIONS**

Based on the results obtained, we can conclude that a large number of sheep and goats in Serbia are infected with pulmonary strongilides. *Protostrongylus rufescens* and *Dictyocaulus filaria* are the dominant species, while *Muellerius capillaris* and *Cystocaulus nigrescens* are present in a smaller percentage.
